Accepted for publication 30 April 2009

The relative age effect (RAE) is a biased distribution of elite athletes' birthdates, with an overrepresentation of those born at the beginning of the competitive year and an underrepresentation of those born at the end. Despite an abundant literature, the impact of sex on this phenomenon remains neglected by most researchers. This study investigated the whole sample of female soccer players affiliated to the French Soccer Federation for the 2006–2007 season (n = 57,892). It first aimed at testing the presence of RAE depending on age. Next, we looked at the birthdates of dropout players during the next season (n = 15,285), to test whether relative age accounts for dropout from the activity. The analyses revealed significant differences between the expected and the observed distributions for all age categories. Furthermore, a significantly biased distribution of dropout players’ birthdates was found for the <10, <14, and <17 categories. On the whole, dropout players are underrepresented in Q1 and Q2, but overrepresented in Q3 and Q4. This study completes the literature on RAE among females, but the inconsistency of the results calls for more research on this population.

The relative age effect (RAE) is a phenomenon initially observed by Grondin et al. (1984), and consists in a biased distribution of elite players’ birthdates. What is generally noticed is an overrepresentation of athletes born at the beginning of the competitive year but an underrepresentation of people born by the end of it. It is considered to be derived from the age categories distinguished by sport instances to organize and try to balance youth competition. Most of the time, children and adolescents born during two consecutive years are gathered in a common category. Thus, within a system using the first of January as a cutoff date, a child born in January of the first year of a category will show a discrepancy of up to 23 months with a child born in December of the second year. This difference in relative age is likely to induce important variations in terms of physical (Tanner & Whitehouse, 1976) and cognitive development (Bisanz et al., 1995), the discrepancies being particularly marked during puberty (Delorme & Raspaud, 2009). The advantages regarding physical characteristics (i.e., in height, weight, or strength) can undoubtedly impact those young players’ perceived potential in the activity (Helsen et al., 2005). Those born at the beginning of the competitive year are more easily identified as “talented” or “promising”, and consequently, they are more often selected to be a part of elite groups or to play within national youth teams. They benefit from this early exposition, which may bring them determinant technical and strategic skills (Williams, 2000; Ward & Williams, 2003).

This differentiated access to high-level training and competition is considered as a kind of discrimination, because it disadvantages players born late after the cutoff date, reducing drastically their chances to access to the elite (Musch & Hay, 1999; Simmons & Paull, 2001; Edgar & O’Donoghue, 2005). Even if such discrimination seems involuntary, it needs to be examined cautiously, given the profits that can be achieved through the practice of certain sports.

RAE and dropout

In addition to partly conditioning the access to high-level practice, the differences of experience induced by relative age are likely to be a factor of the dropout for young participants born late in the competitive year. Firstly, because of a less advanced state of physical development, they might experience a reduced time of play during official games, as suggested by the study of Vaeyens et al. (2005). Additionally, relative age may be accompanied by divergences in
terms of self-perceptions. Indeed, players born at the end of the competitive year may encounter more frequent situations of failure or inferiority, and such negative situations are likely to undermine these players’ feelings of competence and self-worth.

Past literature in sport psychology reveals that reduced opportunities to play (Guillet et al., 2002), as well as low perceptions of sport competence significantly contribute to the cessation of the practice of team sports (Ommundsen & Vaglum, 1991a, b; Guillet et al., 2006). Thus, the RAE traditionally observed among elite samples could also be the result of more important rates of dropout among players born late in the competitive year. In this vein, Delorme and Raspaud (2008) show that among male basketball players aged between 9 and 15 years, and female players aged from 8 to 15 years, those born at the end of the year are overrepresented among dropout players, whereas those born early after the cutoff date are underrepresented. Such a biased distribution in the birthdates of dropout players also emerged among male soccer players aged from 8 to 17 years [Delorme & Raspaud, 2008].

**Competition and RAE**

Even if the role of the cutoff date chosen to create age categories among young participants is deemed central in the RAE phenomenon, it is not considered as the only necessary condition for its presence. Instead, in their review of the literature, Musch and Grondin (2001) present it as the result of “a mixture of physical, cognitive, emotional, and motivational causes work together to produce the effect” (p. 159). The first element they underline is competition. Indeed, in the case of a low competition, any player can belong to the team and may benefit from numerous opportunities to play, because there is a place for everyone. As the authors advance, “the larger the pool of potential players, for a given sport in a given category, the strongest the resulting RAE should be” (p. 154). In this vein, if the number of potential players is superior to the actual structures (i.e., number of teams and number of players in a team) and infrastructures (i.e., equipment available and time slots), there will be an accrued competition among them to belong to a team. Under these conditions, priority will be given to the more performing players, potentially those born early in the competitive year, who benefit from a better perception from coaches regarding their potential in the activity, compared with players born later in the year (Helsen et al., 2005).

This said, it is logical to expect a RAE to appear in popular activities, which is subject to cultural disparities (i.e., the popularity of one sport varies from one country to another). For instance, in Canada, a RAE was systematically observed for ice hockey (e.g., Barnsley et al., 1985; Barnsley & Thompson, 1988; Grondin & Trudeau, 1991), which represents the most popular activity in this country, whereas no effect was observed for volleyball (Grondin et al., 1984), a low-developed sport. Some authors also underlined the link between the strength of the RAE and the level of practice studied in a given sport; the more the level increases, the stronger the RAE. This correlation has particularly been shown in ice hockey and soccer (Musch & Grondin, 2001).

**Factors of success in the activity and RAE**

The second main factor underlined by Musch and Grondin (2001) is the prevalence of physical attributes for performance in the activity. Most of the studies in which a RAE was observed concerned activities in which height, weight, and strength represent key factors of success, like team sports involving physical contact such as ice hockey (e.g., Grondin & Trudeau, 1991), football (e.g., Daniel & Janssen, 1987), soccer (e.g., Helsen et al., 2005), or other individual activities, like tennis or swimming (Baxter-Jones, 1995). Conversely, in other activities, the physical attributes cited can be seen as being relatively independent from success, because other parameters, such as motor skills, are more prevalent, or can even be seen as counterproductive, because being short and thin is preferable for performance. This is the case, for example, for dance or gymnastics, which should therefore, not be prone to a RAE. Accordingly, Van Rossum (2006) did not find RAEs among Dutch dancers. This hypothesis was also sustained by the work of Baxter-Jones and Helms (1996) and of Malina et al. (2004), who showed that a late puberty was an advantage for young dancers and gymnasts. Besides, a positive correlation was found between late puberty and elite gymnastics practice (Malina, 1994; Baxter-Jones et al., 1995).

**Sex and RAE**

Musch and Grondin (2001) stated that stronger RAEs should be observed in male youth sports, compared with female samples. According to Baxter-Jones (1995), such differences would result from a complex interaction between the biological differences due to puberty and sociological factors. In fact, while considering the two factors presented above, as sport represents a masculine area, competition is expected to be higher among boys than girls, leading to a greater RAE (Musch & Grondin, 2001). Indeed, if an early physical development gives an important advantage to young sportsmen in many activities, it appears to be a disadvantage for young
sportswomen, given the existing social pressures around their body (Vincent & Glamser, 2006). This stereotyped representation of the female body may lead early-developed girls to drop out from sports activities (Shakib, 2003), thus reducing the potential strength of the RAE. Finally, because of an earlier puberty in girls and the larger variance in the development of puberty in boys, at the moment of the selection process, there would be greater physical disparities due to relative age among boys, compared with girls (Baxter-Jones, 1995).

However, in spite of an abundant literature on this phenomenon in the sport setting, the impact of sex remains neglected by most researchers (Musch & Grondin, 2001; Wattie et al., 2007). Studies concerning female samples are not only scarce to date, but have also revealed inconsistent results. To our knowledge, only five studies exist on the examination of RAE in female samples. Two of them concerned popular activities, i.e., where an important competition should enhance RAE, but where physical attributes are considered as handicapping or at least not advantageous, namely gymnastics and dance. Baxter-Jones (1995), studying elite British gymnasts, observed no RAE either in males or in females. Van Rossum (2006) reached the same conclusions with pre-professional Dutch dancers.

Conversely, the three other studies concerned team sports where a RAE was traditionally observed among male athletes. First, Delorme et al. (2009), investigating the French elite championships in team sports, report no RAE for female soccer, basketball, and handball players, whereas several significant effects emerged for male players in ice hockey and trends were also observed for male rugby union and handball. In the same vein, Vincent and Glamser (2006), analyzing a sample of 17-year-old American soccer players, report a more systematic and stronger RAE for males, compared with females. Finally, Delorme and Raspaud (2009) observed a significant RAE in all youth categories of French basketball players, aged from 7 to 17 years. The effects were even more pronounced for girls compared with boys. These results suggest that among female adult, elite samples, there is actually no or weak RAEs. However, the only study conducted on regular young sport participants reveals a significant effect for both girls and boys.

**Purpose of the study and hypotheses**

Given these contradictory results and the reduced number of studies having investigated female athletes in the past, it seems crucial to look at original samples of this population in order to better understand the impact of sex on the occurrence of RAE.

In this regard, the purpose of the present study was twofold. Investigating the female soccer players affiliated to the French Soccer Federation (FSF) for the 2006–2007 season, it first aimed at examining the presence or absence of a RAE depending on age. This was carried out by looking at every age category in a diachronic perspective. Next, we looked at the birthdates of the players who had not reiterated their affiliation for the 2007–2008 season, in order to test whether relative age accounts for female dropout from the activity.

According to the previous research as discussed above, the two following hypotheses were formulated:

1. We expect a systematic RAE in all youth-age categories but no effect in the adult category.
2. We expect an overrepresentation of late-born children in dropouts and an underrepresentation of those who are born early in the competitive year for each youth category. Concerning the adult category, a uniform distribution of dropouts is expected.

**Materials and methods**

**Data collection**

For the purpose of the present study, the birthdates of all French female players affiliated to the FSF (n = 57 892) during the 2006–2007 season were collected from the federation database. Among this sample the FSF also communicated the birthdates of the players who did not reiterate their affiliation for the 2007–2008 season (n = 15 285). This information was communicated after the 2007–2008 season was over so as to avoid considering dropout players who had taken their licenses late during the season. Among female players, the FSF distinguished six age categories: “<8 years,” “<10 years,” “<12 years,” “<14 years,” “<17 years,” and “adults.”

**Data analysis**

In the past literature, the presence of a RAE was determined by showing a significant difference between the expected number of players born by month or quarter (i.e., three consecutive months period) and the observed distribution. For each of the six categories presented, the players’ birthdates were classified into four quarters. Since the cutoff date used to form age categories has been modified by the FSF (Jullien et al., 2008), the players born before 1982 were classified from Q1 (August–October) to Q4 (May–July) and the players born in 1982 and after were classified from Q1 (January–March) to Q4 (October–December).

A chi-square goodness-of-fit test was then performed, comparing the expected and the observed distribution of birthdates. In line with previous research, for each age category, the expected distribution was calculated based on the national birth statistics by month and year for females, using weighted mean scores. These data were obtained through the National Institute of Economical Statistics and Studies. Regarding dropout players, the expected distribution considered was based on the birthdates observed for the whole
Results

Table 1 presents the birthdates’ distribution by quarter for each age category identified for female players by the FSF, during the 2006–2007 season. The analyses reveal statistical differences between expected and observed distributions for all age categories. For all youth categories, the results reflect a classical RAE with an overrepresentation of players born in Q1 and Q2, and an underrepresentation of players born in Q3 and Q4. For the “adult” category, however, the asymmetry observed was derived from this classical pattern; players born in Q2 and Q3 were overrepresented, but those born in Q1 and Q4 were underrepresented.

Table 2 presents the rates of dropout for each age category. The dropout rate increased in the first age categories and from the “<14 years” and it approximated 30%. The general turnover rate was equal to 26.4%.

Table 3 presents the birthdate distribution by quarter for each age category identified for female players by the FSF, during the 2006–2007 season.

A significantly biased distribution was found for the <10, <14, and <17 categories. As a whole, the dropout players were underrepresented in Q1 and Q2, but more often overrepresented in Q3 and Q4. Conversely, the birthdate distribution was distributed as expected for the <8, <12, and adult categories.

Discussion

A RAE has traditionally been observed among male athletes of the elite level in sports where physical attributes such as weight, height, and strength represent key factors for success. This phenomenon can thus be seen as the consequence of a selection bias favoring players born at the beginning of the competitive year and potentially higher rates of dropout.
among players born at the end. Very little is known about RAE among female athletes, and the handful of studies that investigated this population report heterogeneous results. This research thus aimed at exploring the French female soccer players for the 2006–2007 season. We studied their birthdate distribution compared with the national standards. Moreover, we distinguished a sample of dropout players in order to examine whether their quarter of birth could account for this behavior.

A systematic RAE

Because a high competition among players and the prevalence of physical attributes for performance have been pointed out as necessary conditions for a RAE to occur (Musch & Grondin, 2001), we expected a significant RAE to emerge among youth categories, as was observed for French basketball players by Delorme and Raspaud (2009). Conversely, because a very weak effect appeared for 17-year-old American soccer players (Vincent & Glamser, 2006) and no effect at all was observed for French soccer players in the national championship (Delorme et al., 2009), we posited that there should be no significant effect in the adult category.

These hypotheses were partially supported because a significant distortion emerged between the observed distribution by quarter and the national distribution for all age categories, including adults. The distortion observed among youth players respects the traditional RAE, with players born in Q1 and Q2 overrepresented and players born in Q3 and Q4 underrepresented. This result echoes the results obtained in basketball by Delorme and Raspaud (2009) and reinforces the idea that such a phenomenon particularly arises in popular team sports involving physical contact. On the other hand, the significant effect obtained for adults contrasts with the past literature in this activity with female samples (Vincent & Glamser, 2006; Delorme et al., 2009). Even if the pattern is less clear than in the youth categories, the main irregularities observed go in the sense of a RAE, with a very important overrepresentation of players born in Q2 and a very marked underrepresentation of players born in Q4.

Moreover, it should be outlined that in the past two studies conducted on female soccer, the participants were elite players involved in the national championship, whereas the sample of the current study includes players of all levels. Given the size of this sample, which includes all the French female soccer players, one can reasonably think that it represents an “average” level. In this vein, the systematic RAE observed in this study disappears in the French female elite level where Delorme et al. (2009) did not find any RAE. Contrary to males among whom the elevation of the level of practice was found to enhance the magnitude of the RAE (Musch & Grondin, 2001), it appears that among females, the higher the level, the lower the RAE is. A social explanation seems necessary to justify this apparently paradoxical result.

As suggested by Vincent and Glamser (2006), social pressures that encourage adolescents to conform to gender-based stereotypes could prevent females from achieving excellence in competitive sport, especially early maturing females. The physical characteristics needed for athletic accomplishments are sometimes opposite to the representation of the ideal female body, which should be thin and tiny (Choi, 2000). Shakib (2003) noted that the consequence of such an opposition may be for some girls to drop out from sports at some point during puberty. Thus, such role conflicts could lead outstanding female players to drop out from soccer or to renounce to an elite practice. Because of the physical differences due to relative age, the pressures, and the associated embarrassment would be particularly high for players born at the beginning of the year, which may explain why the birthdate distribution reveals no RAE among elite players. In brief, if an early physical development acts as an important advantage for young males in many sports, it also acts as a socially constructed disadvantage for young females that could facilitate their dropout from sports activities.

Nevertheless, this interpretation remains speculative, and more research is needed to specifically examine whether, among the female players involved at a good level of practice, there are actually more dropouts among those born at the beginning of the competitive year compared with those born in the last quarter.

A dual mechanism resulting in RAE

The second purpose of the study was to examine whether the birthdate distribution of female players who dropped out from soccer would significantly differ from the values observed in the entire sample of licensed players. Because of the physical inferiority occasioned by relative age, and the potentially reduced opportunities to play and lowered self-perceptions, we hypothesized the dropout players to be overrepresented in the last two quarters of the competitive year, and those born during the first two quarters to be underrepresented. Because this phenomenon may cease with physical growth, we set this hypothesis only for youth categories, and expected no significant effect among adults.

This hypothesis was partially supported, since in three age categories (< 10, 14, and 17 years), the players born in the last 6 months of the competitive year were overrepresented, whereas those born in the
first 6 months were underrepresented in the dropout sample. The reverse asymmetry observed in the global population (in fact, the classical RAE distribution) would thus partly be due to this unequal distribution of dropouts. A fruitful perspective of research would be to verify whether the factors cited earlier (e.g., opportunities to play and self-perceptions) can actually be considered as mechanisms through which more important dropout rates are obtained among players born in Q3 and Q4.

It should also be underlined that in spite of a homogeneous distribution of dropout players in the <8 and <12 sub-groups, these categories were subject to a significant RAE. In other words, girls born in Q1 and Q2 are more likely to begin playing soccer compared with their younger counterparts. Those born in Q3 and Q4, potentially because of their less advantageous physical attributes, show a kind of “self-selection” process before even trying the activity. The RAE can thus be seen as the result of two simultaneous phenomena. On the one hand, children born at the end of a competitive year would be less likely to undertake the practice of an activity in which weight, height, or strength could be seen as relevant for performance. On the other hand, those who begin to practice are more likely to drop out from it and have fewer chances to be selected and reach the elite.

**Perspectives**

Based on the whole population of the FSF players for the 2006–2007 season, this study investigated, from a diachronic perspective, the RAE among females. A significant RAE was observed for all categories, suggesting that this effect seems to decrease with the level among females, contrary to what was observed among males. Besides, the analysis of the birthdate distribution suggests that this phenomenon results from a dual mechanism: a higher rate of dropout among players born late in the competitive year, and a larger proportion of players born early in the competitive year among beginners. These results demonstrate the importance for RAE research to conduct more studies on female athletes, who remain neglected to date. The contradictory results obtained in the rare studies involving female participants show that the current knowledge on the mechanisms explaining the presence or absence of RAE still needs to be improved.

**Key words:** relative age effect, female, soccer, dropout.
